Current address: 3 Freda Court, Blackburn South, Victoria, Australia

**Abstract** This paper summarises the variations in breeding periodicity in the Australasian - South Pacific region, including recent evidence contrary to previous knowledge. Birds shown to breed in the Samoan islands throughout the year are white-tailed tropicbird (*Phaethon lepturus*), white-rumped swiftlet (*Aerodramus spodiopygius*), buff-banded rail (*Gallirallus philippensis*), brown noddy (*Anous stolidus*), white tern (*Gygis alba*) and wattled honeyeater (*Foulchaio carunculata*). In addition, crimson-crowned fruit-dove (*Ptilinopus porphyraceus*), blue noddy (*Procelsterna caerulea*), cardinal honeyeater (*Myzomela cardinalis*) and Polynesian triller (*Lalage maculosa*) breed in at least 9 months of the year. The Samoan whistler (*Pachycephala flavifrons*) has been found breeding in 8 months and the Samoan starling (*Aplornis atrifusca*) in 7 months of the year.

### INTRODUCTION

Reproduction in birds, as in all animals, takes place at the time of the year when it is biologically most advantageous for them to do so (Serventy & Warham 1971). Breeding periodicity allows birds and other organisms to synchronize breeding attempts with the most favourable ecological conditions under which to raise their offspring. In most of the world, ecological conditions vary seasonally and so impose an annual breeding schedule on their populations (del Hoyo *et al.* 1992). In the tropics however, seasons are not as distinct and annual breeding cycles may be longer than in temperate regions (Ricklefs 1966) or may not develop for a population or for individuals (Pyle *et al.* 2016).

The characteristic breeding cycles for some groups of birds have been known for some time; this is particularly the case for seabirds in which their colonial nature facilitates the collection of data regarding breeding seasonality. For instance, it has long been known that albatrosses nesting in temperate locations breed every second year even though the breeding site will have half the population breeding in it each year (Jouventin & Dobson 2002; Ratcliffe *et al.* 2008).

Regional variations have also been reported in seabirds. Serventy & Warham (1971) note that almost all species of seabirds in eastern and south-eastern Australia restrict their breeding to the spring and summer; whereas in north-western Australia, the predominant period of egg-laying is in the autumn and winter, and in south-western Australia spring and early summer egg-laying is the rule. In

the intervening region, from the Lacepede Islands in the north to Shark Bay, there are both autumn-breeding and spring-breeding populations on the same islands.

The incidence of tropical cyclones and strong winter winds, as well as upwelling ocean currents, each appear to have an effect on the seasonality of egg-laying in seabirds. Silver gulls (*Larus novaehollandiae*) in Western Australia are double brooded with an interval of about 4 months between layings (Nicholls 1964). When silver gulls are taken from south-eastern Australia where they are single brooded and held in captivity in south-western Australia, they become double brooded in synch with the local gulls (Nicholls 1964). In New Zealand, the nitrogen-rich upwellings off Kaikoura facilitate and control the timing and success of the breeding of red-billed gulls (*Larus novaehollandiae*) and Hutton's shearwaters (*Puffinus huttoni*) (Sherley 1992; Mills *et al.* 2008). During the breeding season, the relative availability of New Zealand krill (*Nyctiphanes australis*) was correlated positively with the Southern Oscillation Index and the frequency of occurrence of north-east winds which induce upwelling. Incursions of warm oceanic water, often induced by westerly winds which are characteristic of El Niño years, were associated with reduced euphausiid availability and reduced breeding success (Mills *et al.* 2008).

Less is known about the breeding seasons of tropical seabirds; but what is known often shows sub-annual breeding periodicity, rather than annual or biennial periodicity. Tropical seabirds known to breed every 6 months include swift terns (*Sterna bergii*) on Aldabra Atoll (Diamond & Prys-Jones 1986) and white terns (*Gygis alba*) on Christmas Island (Pacific) (Ashmole 1968). Those breeding every 7 to 8 months include white-tailed tropicbirds (*Phaeton lepturus*) on Ascencion Island (Stonehouse 1962) and Aldabra Atoll (Prys-Jones & Peet 1980), and bridled terns (*Sterna anaethetus*) on Aldabra Atoll (Diamond & Prys-Jones 1986). Those breeding every 9 to 10 months include the Christmas shearwater (*Puffinus nativitatis*) on Pitcairn Islands (Brooke 1995), and Audubon's shearwater (*Puffinus lherminieri*) and swallow-tailed gulls (*Creagrus furcatus*) on the Galapagos Islands (Snow 1965; Snow & Snow 1967). In Fiji, it has been shown that while the colony of black noddies (*Anous minutus*) on Vatu-i-Ra is occupied by birds throughout the year (Tarburton 1978), breeding takes place at 9 to 10-month intervals, and individual birds breed each second cycle (Tarburton 1987).

Small islands in the tropical South Pacific have less seasonal climate variation than most other places on earth (Steadman 2006). This means that along with the reliable year-round rainfall (except on a small part of large islands such as Savaii)

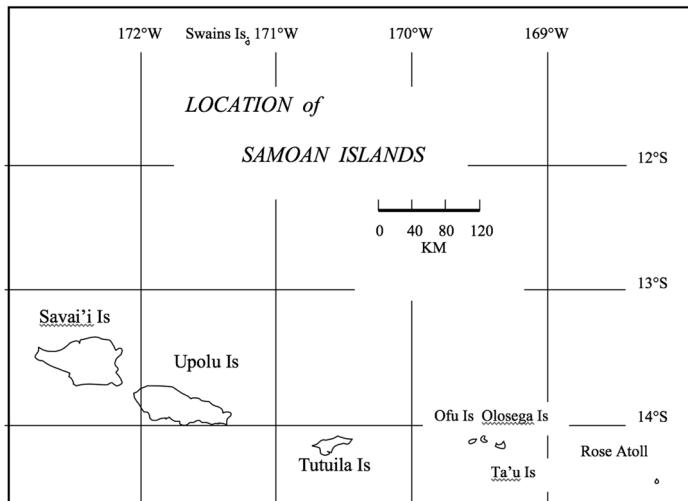

plants, invertebrates and vertebrates have greater possibilities of reproducing all year (Ricklefs 1966; Weimerskirch 2007). To prevent overpopulation there can be mechanisms to restrict that breeding period, to restrict the number of progeny or to reduce the number of breeders.

Watling (2001) uses information from the Whitney Expedition and his own observations to suggest that there is a distinct seasonal pattern in both breeding and moult for many south Pacific bird species. He points out that this seasonality is found in the majority of land birds in Fiji and Tonga, but less clearly in Samoa. Because the Samoan climate is almost aseasonal, it is tempting to agree with Dhondt (1976), that breeding is not restricted to 1 part of the year. Dhondt's assertion was based on his finding that buff-banded rails (*Gallirallus philipensis*) and Polynesian trillers (*Lalage maculosa*) were breeding in 6 to 8 months of the year. He only visited a white-rumped swiftlet (*Aerodramus spodiopygius*) colony once, but combining this with Ashmole's data (1963), he determined breeding in April, June and November, albeit in different years. Ashmole (1963) was able to make the generalisation that it is obvious that breeding is not restricted to 1 part of the year. She found banded rails breeding in March and August and white-rumped swiftlets breeding in February, April, June and November.

Banks (1984) noted that even though 1,300 specimens have been taken from American Samoa, the annual cycle remains incompletely known even for those few species with large samples of specimens. Largely this is due to the limited timing of collecting. Probably about the same number of specimens have been taken from Samoa (formerly Western Samoa) with similarly minimal information about the breeding seasons of the birds that breed there.

In 1985, the U.S. Fish & Wildlife Service organised a large survey of forest birds in American Samoa, but at the end of that they still claimed "little is known about life histories of forest birds" (Engbring & Ramsey 1989).

It has been shown that on Savaii, the largest island in the Samoan Archipelago, that the purple swamphen (*Porphyrio porphyrio*), flat-billed kingfisher (*Todiramphus recurvirostris*) and Samoan flycatcher (*Myiagra albiventris*) do not inhabit that island above 1,200 m (Pratt & Mittermeier 2016). What factor(s) restrict these birds? They also conclude that the Samoan woodhen (*Galinula pacifica*), a flightless rail, has been extinct for over 100 years and that recent "sightings" are mis-identifications. Steadman (2006) estimated that between 500–1,600 species of flightless rails inhabited Pacific islands prior to the first human colonization. However, not a single species survives on inhabited islands outside of New Zealand (Pratt

**Fig. 1.** Location of Samoan islands.

& Mittermeier 2016). It is too late to find out if they could or did breed all through the year.

Since I was to live on Upolu in Samoa for 4 years it was decided to start filling in some of the blanks in the breeding cycles of Samoan birds. Accordingly, this paper collates information from literature sources and field observations to provide an updated account of bird breeding activity on the Samoan islands.

## MATERIALS AND METHODS

Breeding data from the literature were compiled and added to my own field observations, made between January 1994 and December 1997, while locating and visiting 38 caves on the Samoan islands of Savai'i, Upolu and Tutuila, as well as doing over 400 1-hour censuses of seabird movements around the entire coast of Upolu.

To make headway on the bush birds, 35 trips were made up the walking track from Vailima, past the Robert Louis Stevenson memorial to the lookout on the west face of Mt Vaea, specifically to observe evidence for breeding. Mt Vaea is close to the capital of Samoa, Apia, on the island of Upolu. These walks were made between 1 July 1995 and 19 April 1997. One to 7 walks were made each month. Thus, while not evenly spread over the study period, the walks did add many data points to this paper.

Key indicators used to determine breeding included anatomical features (i.e. enlarged testes or ovaries), nests with contents (i.e. eggs, nestlings or brooding adults), breeding behaviours (i.e. seabirds landing in forests, courtship behaviour, copulation) or the presence of recently fledged birds.

Non-breeding indicators from specimens or captured birds are not recorded because it is too uncertain as to whether the individual was immature or in post-breeding condition. From looking at skins in all Australian and New Zealand Museums as well as live birds and the literature, I see there is also considerable variation in observer ability with regard to judging the age and seasonal status of skins – particularly in species new to most observers. It is also clear that in those species now known to breed all year that birds not in breeding condition do not preclude others from being in breeding condition.

Names and sequence of birds are taken from Christidis & Boles (2008) or if not included there, from the IOC Checklist (<http://www.worldbirdnames.org/ioc-lists/master-list-2/>).

## RESULTS

The location of the 8 main islands mentioned in this paper are shown in Fig. 1. The actual months of breeding for each species for which data was gained is shown in Table 1. Full details regarding the types of data used as evidence for breeding and the source of these observations are provided in Appendix 1.

Birds shown to breed in the Samoan Islands throughout the year (Table 1) are white-tailed tropicbird, white-rumped swiftlet, buff-banded rail, brown noddy, white tern and wattled honeyeater (*Foulhaio carunculata*). In addition, crimson-crowned fruit-dove (*Ptilinopus porphyraceus*), blue noddy (*Procelsterna caerulea*), cardinal honeyeater (*Myzomela cardinalis*) and Polynesian triller (*Lalage*

## DISCUSSION

Muse & Muse (1982) predicted that the white-tailed tropicbird, the buff-banded rail, the Pacific robin (*Petroica multicolour*) and cardinal honeyeater will be found to breed throughout the year. This paper adds credence to each of these suggestions, though only the first 2 are fully confirmed. The same authors also claimed that the Polynesian triller bred throughout the year but gave no evidence for the statement. This study found Polynesian trillers breeding in 2 of the remaining 3 months – so are now almost certain to be found breeding in all 12 months of the year. This study has also shown that 4 unpredicted species nest in each month of the year: white-rumped swiftlet, brown noddy, white tern and wattled honeyeater.

With seabirds, there is the possibility in Polynesia of having a breeding period of less than 12 months. This non-annual breeding regime has been found in black noddies in Fiji where the colony has an 8 to 10-month breeding cycle (Tarburton 1987), with individuals breeding every 20 months. This means the colony has eggs every 10 months and can look deserted diurnally at the time they had eggs the previous year. At sunset however, the noddies that are not on migration to the Solomon Islands will mass offshore and come ashore to roost each night of the year. A similar regime is possible for sooty terns (*Onychoprion fuscatus*) on Rose Island where eggs were observed in October 1975, whereas in October the following year 4,300 fledglings were

recorded (Sekora 1974 & 1976 in Amerson *et al.* 1982). This is further supported by the recording of breeding birds in May 1974 (Amerson *et al.* 1982). A sub-annual breeding cycle could also explain the breeding dates given for the brown noddy in American Samoa by Amerson *et al.* (1982), whereas they interpret their data as probably signalling breeding throughout the year. Separate colonies may also not be synchronised with each other so we need to be aware of the dangers of mixing data from different sea-bird colonies.

Bridled terns, breeding on Penguin Island in Western Australia breed out of the tropics then migrate to “winter” in the tropics in the Celebes Sea (Dunlop & Johnstone 1994). However, Samoan bridled terns stay in the tropics to breed on the 2 stacks off O-Le-Pupu Pue National Park (Tarburton 2001).

The concept of individual birds not participating in breeding even though the colony might be breeding is also worth consideration. Tarburton (2009) has shown that white-rumped swiftlets breed throughout the year (*contra* Whitmee 1875) at most colonies in Samoa, yet individual pairs in that colony usually breed only once a year. If food levels are continually reasonably high but insufficient for all to breed all the time, then pairs can share them throughout the year. This is in contrast to 1 pair of buff-banded rails on Upolu producing 5 broods in 1 year (Robinson 1995). Even though the swiftlets in Samoa breed all year, there is an obvious peak in September.

Amerson *et al.* (1982) suggest many-coloured fruit-doves (*Ptilinopus perousii*) breed in the southern winter, but from this paper it is now clear that they breed in all 4 seasons. The same authors also suggest that the collared kingfisher “probably

breeds in the southern summer". This paper shows that to be true – but this kingfisher also breeds up to at least June – the Austral winter.

Turning from seabirds to landbirds, Pyle *et al.* (2015) found in American Samoan birds that while there was broad overlap between moult and breeding at the population level, there was very little at the individual level. They suggest that while moult may take precedence over breeding, that tropical landbirds appear to be capable of suspending moult to breed when environmental conditions shift to favour successful reproduction. Much further study is needed to understand why so many Samoan bird species are breeding all year round.

I would be very wary of claiming too much for the family of crested terns I observed in Vaiusu Bay 27 July 1997. The 2 adults were accompanied by a juvenile with 75% of the body covered with brown flecking. The juvenile concerned was very like illustration #4 on Plate 36 in Higgins & Davies (1996). This does not prove breeding in Samoa as banded birds in Australia have been found up to 575 km from their natal colony 19 days after fledging, and over 1,000 km away within 7 weeks of fledging (Higgins & Davies 1996). We just do not know whether this species will take their fledglings over the sea as readily as they do along the Australian coast, but vagrants do turn up in New Zealand (Higgins & Davies 1996).
